# Marine antarctic ecosystems call for a complex approach

More and more researches are showing the complexity of the network formed by prey and predator interactions, the so-called food web, in different Antarctic ecosystems.

“With only three species traits (body mass, metabolic and movement type), our models could predict which 25% of the predators possess the highest average body-mass ratios with surprisingly high accuracy in most ecosystem types.”

## **METHODOLOGY**

# General objective, study area and data source

## General objective

Estimate the interaction strength of the Weddell Sea food web and determine key trophic species considering unweighted and weighted network approach.

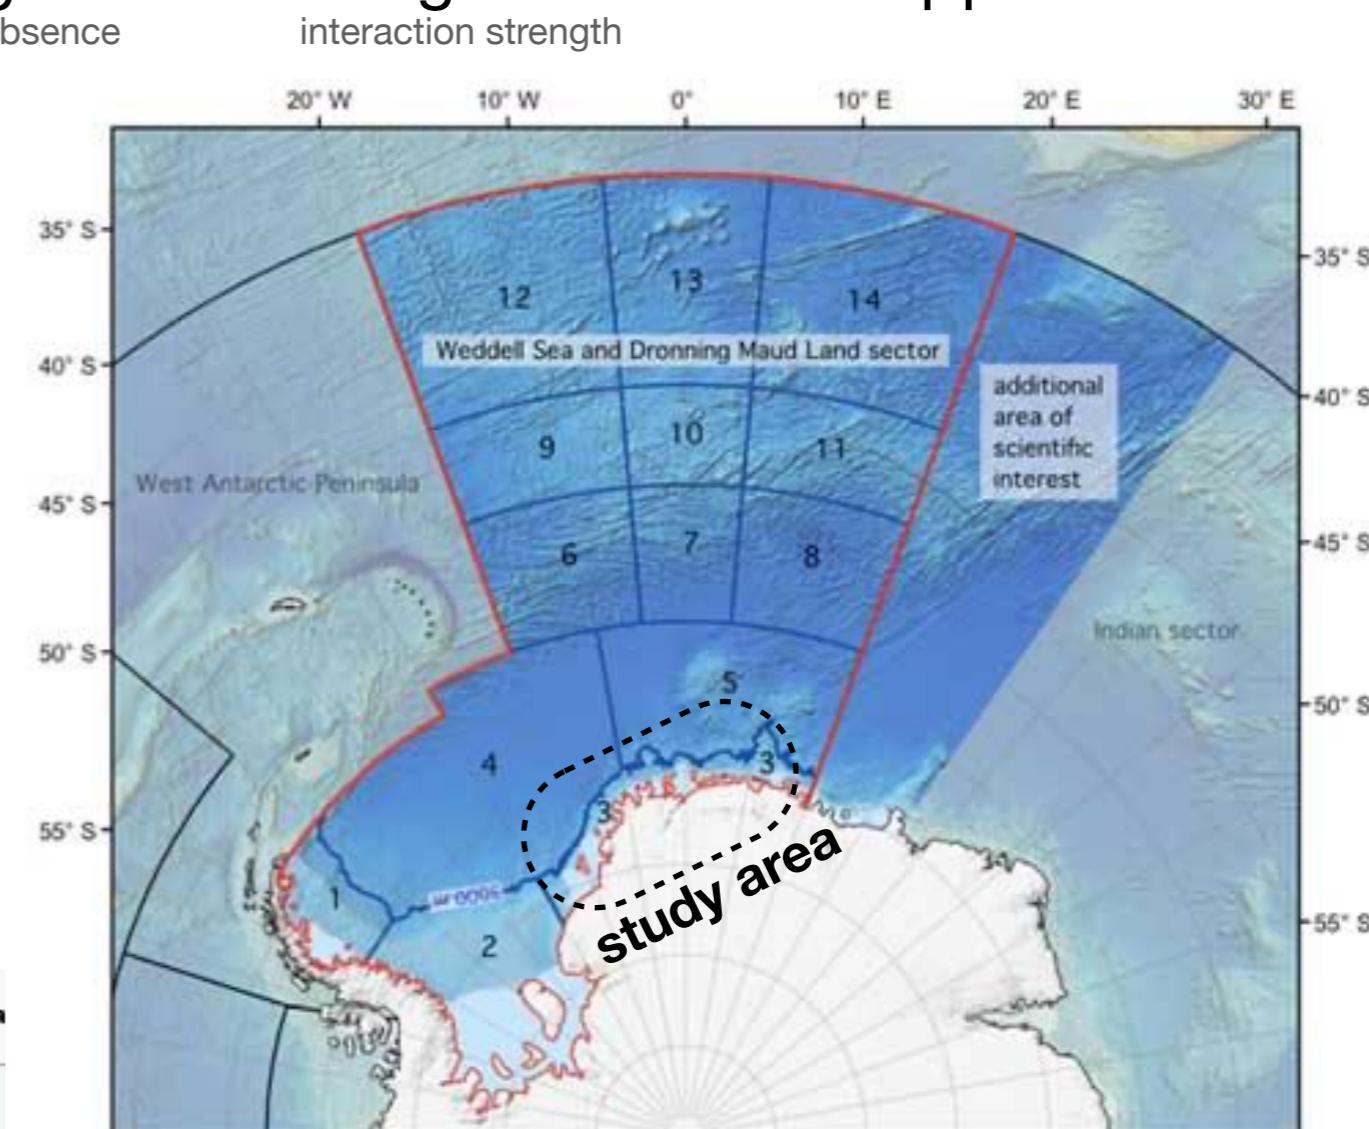

## Study area

High Antarctic Weddell Sea shelf  
( $74\text{--}78^\circ \text{S}$ ), length  $\sim 450 \text{ km}$ .

## Data source

 iDiv  
German Centre for Integrative Biodiversity Research (iDiv) Halle-Jena

# Estimation of interaction strength

We estimated the interaction strength  $IS$  by considering the body mass and the interaction dimensionality of the prey and predator.

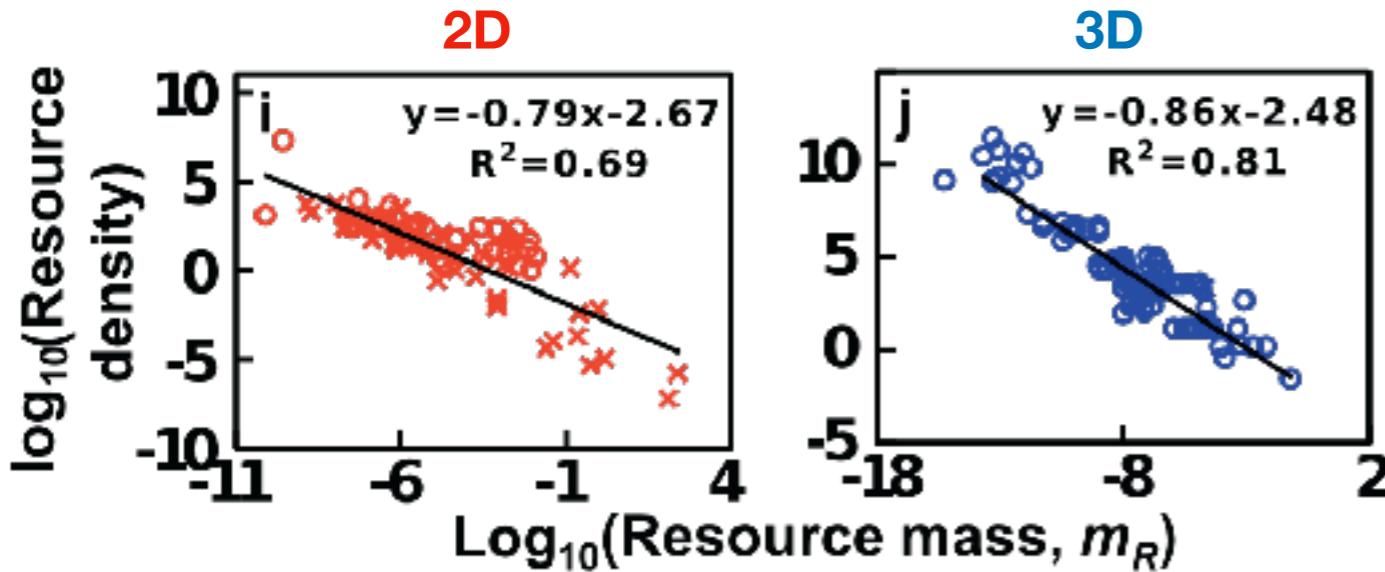

$$IS = \alpha x_R m_R / m_C$$

where  $\alpha$  is the search rate,  $x_R$  is the density of the resource, and  $m_R$  and  $m_C$  are the body mass of the resource and the consumer, respectively.

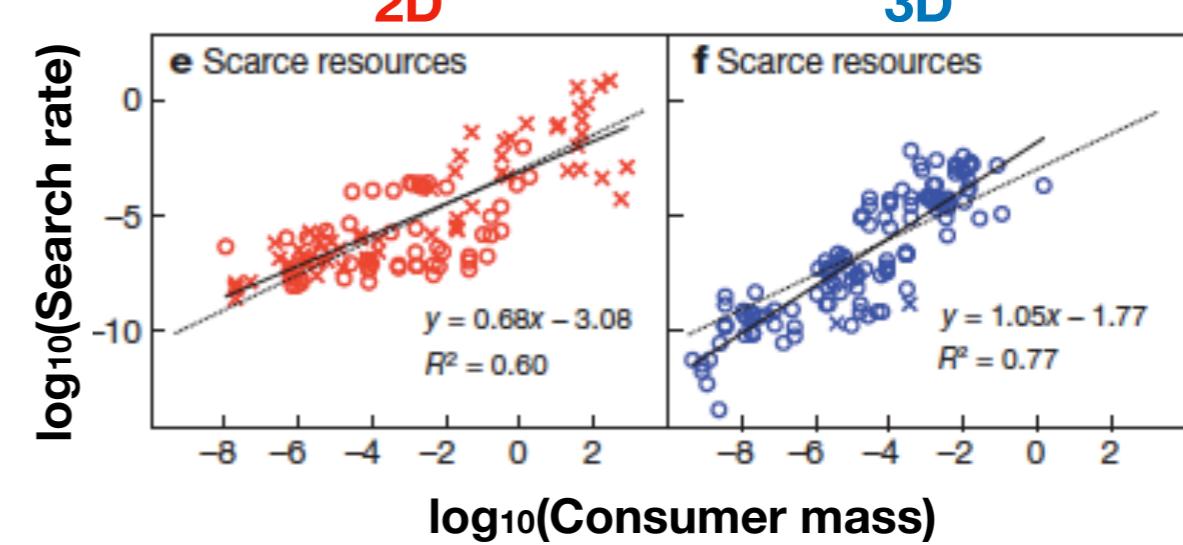

Taken from Pawar et al. (2012). <https://doi.org/10.1038/nature11131>

Estimation of resource density  $x_R$

Estimation of search rate  $\alpha$

# Key trophic species

## Unweighted

### Trophic level:

position of a species in the food web considering the set of prey and predators.

### Trophic similarity (TS):

measures the similarity/uniqueness of a species based on shared (c) and unique (a) resources and consumers with other species (c).  $TS = c / (a + b + c)$

### Degree:

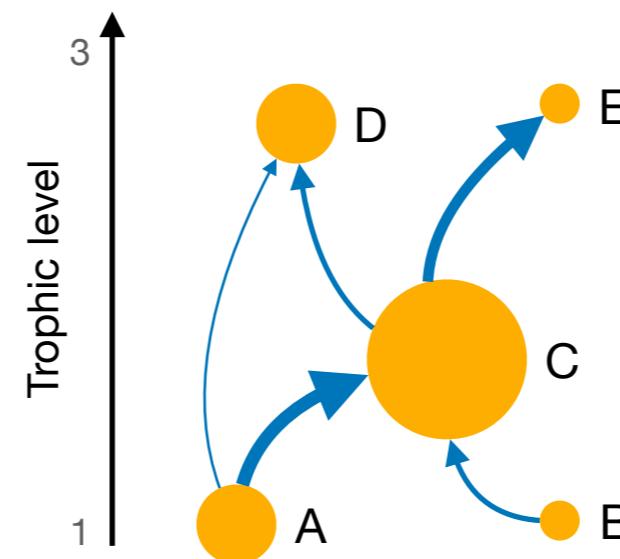

number of total interactions, in- (predator role) plus out-interactions (prey role).

## Weighted

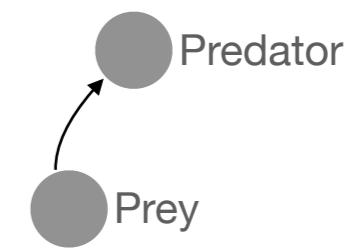

### Interaction strength:

total effect of a species, as a prey and/or predator, in the other species of the food web.

<b>U</b>	Trophic level
<b>N</b>	spp A and B are basal
<b>W</b>	sp C is intermediate
<b>E</b>	spp D and E are top predators
<b>I</b>	Trophic similarity
<b>G</b>	spp A and B share predator C
<b>H</b>	sp C shares predators D and E
<b>T</b>	spp D and E share prey C
<b>E</b>	Degree (node diameter)
<b>D</b>	spp A and D = 2
	sp C = 4
	spp B and E = 1

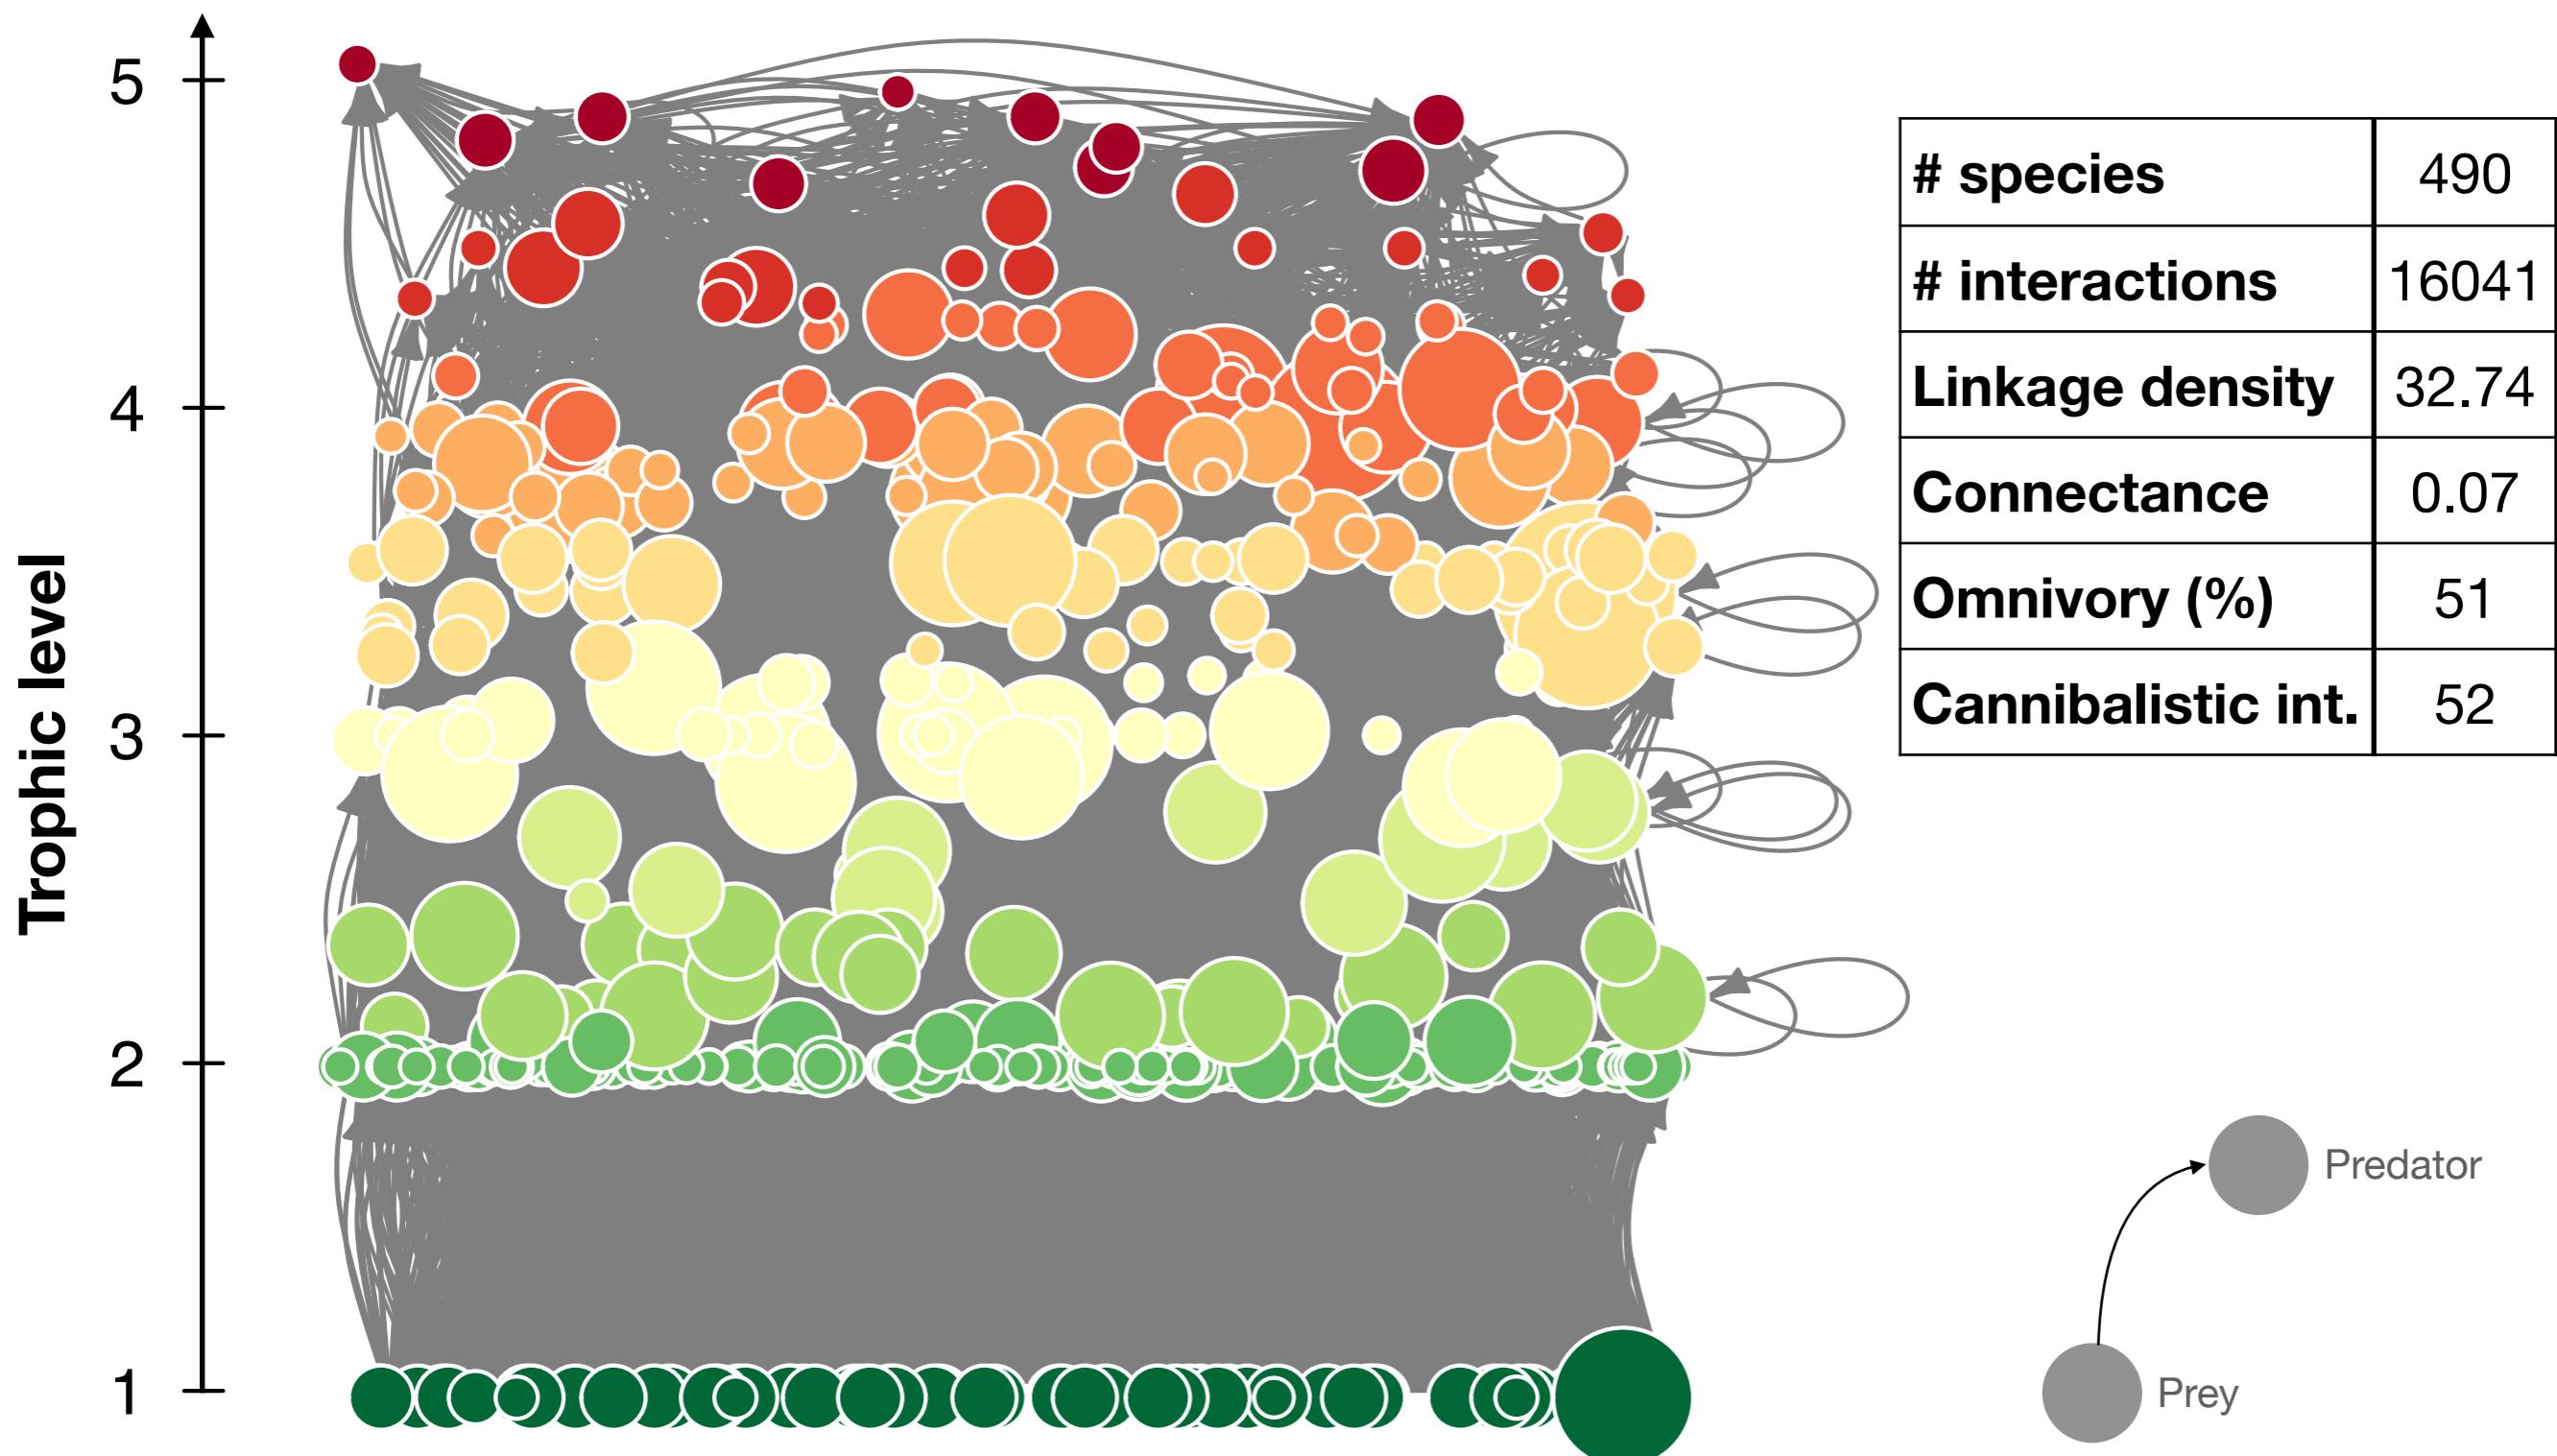

**WEIGHTED**  
**Interaction strength**  
A → C is the strongest  
A → D is the weakest  
sp C has the greatest strength

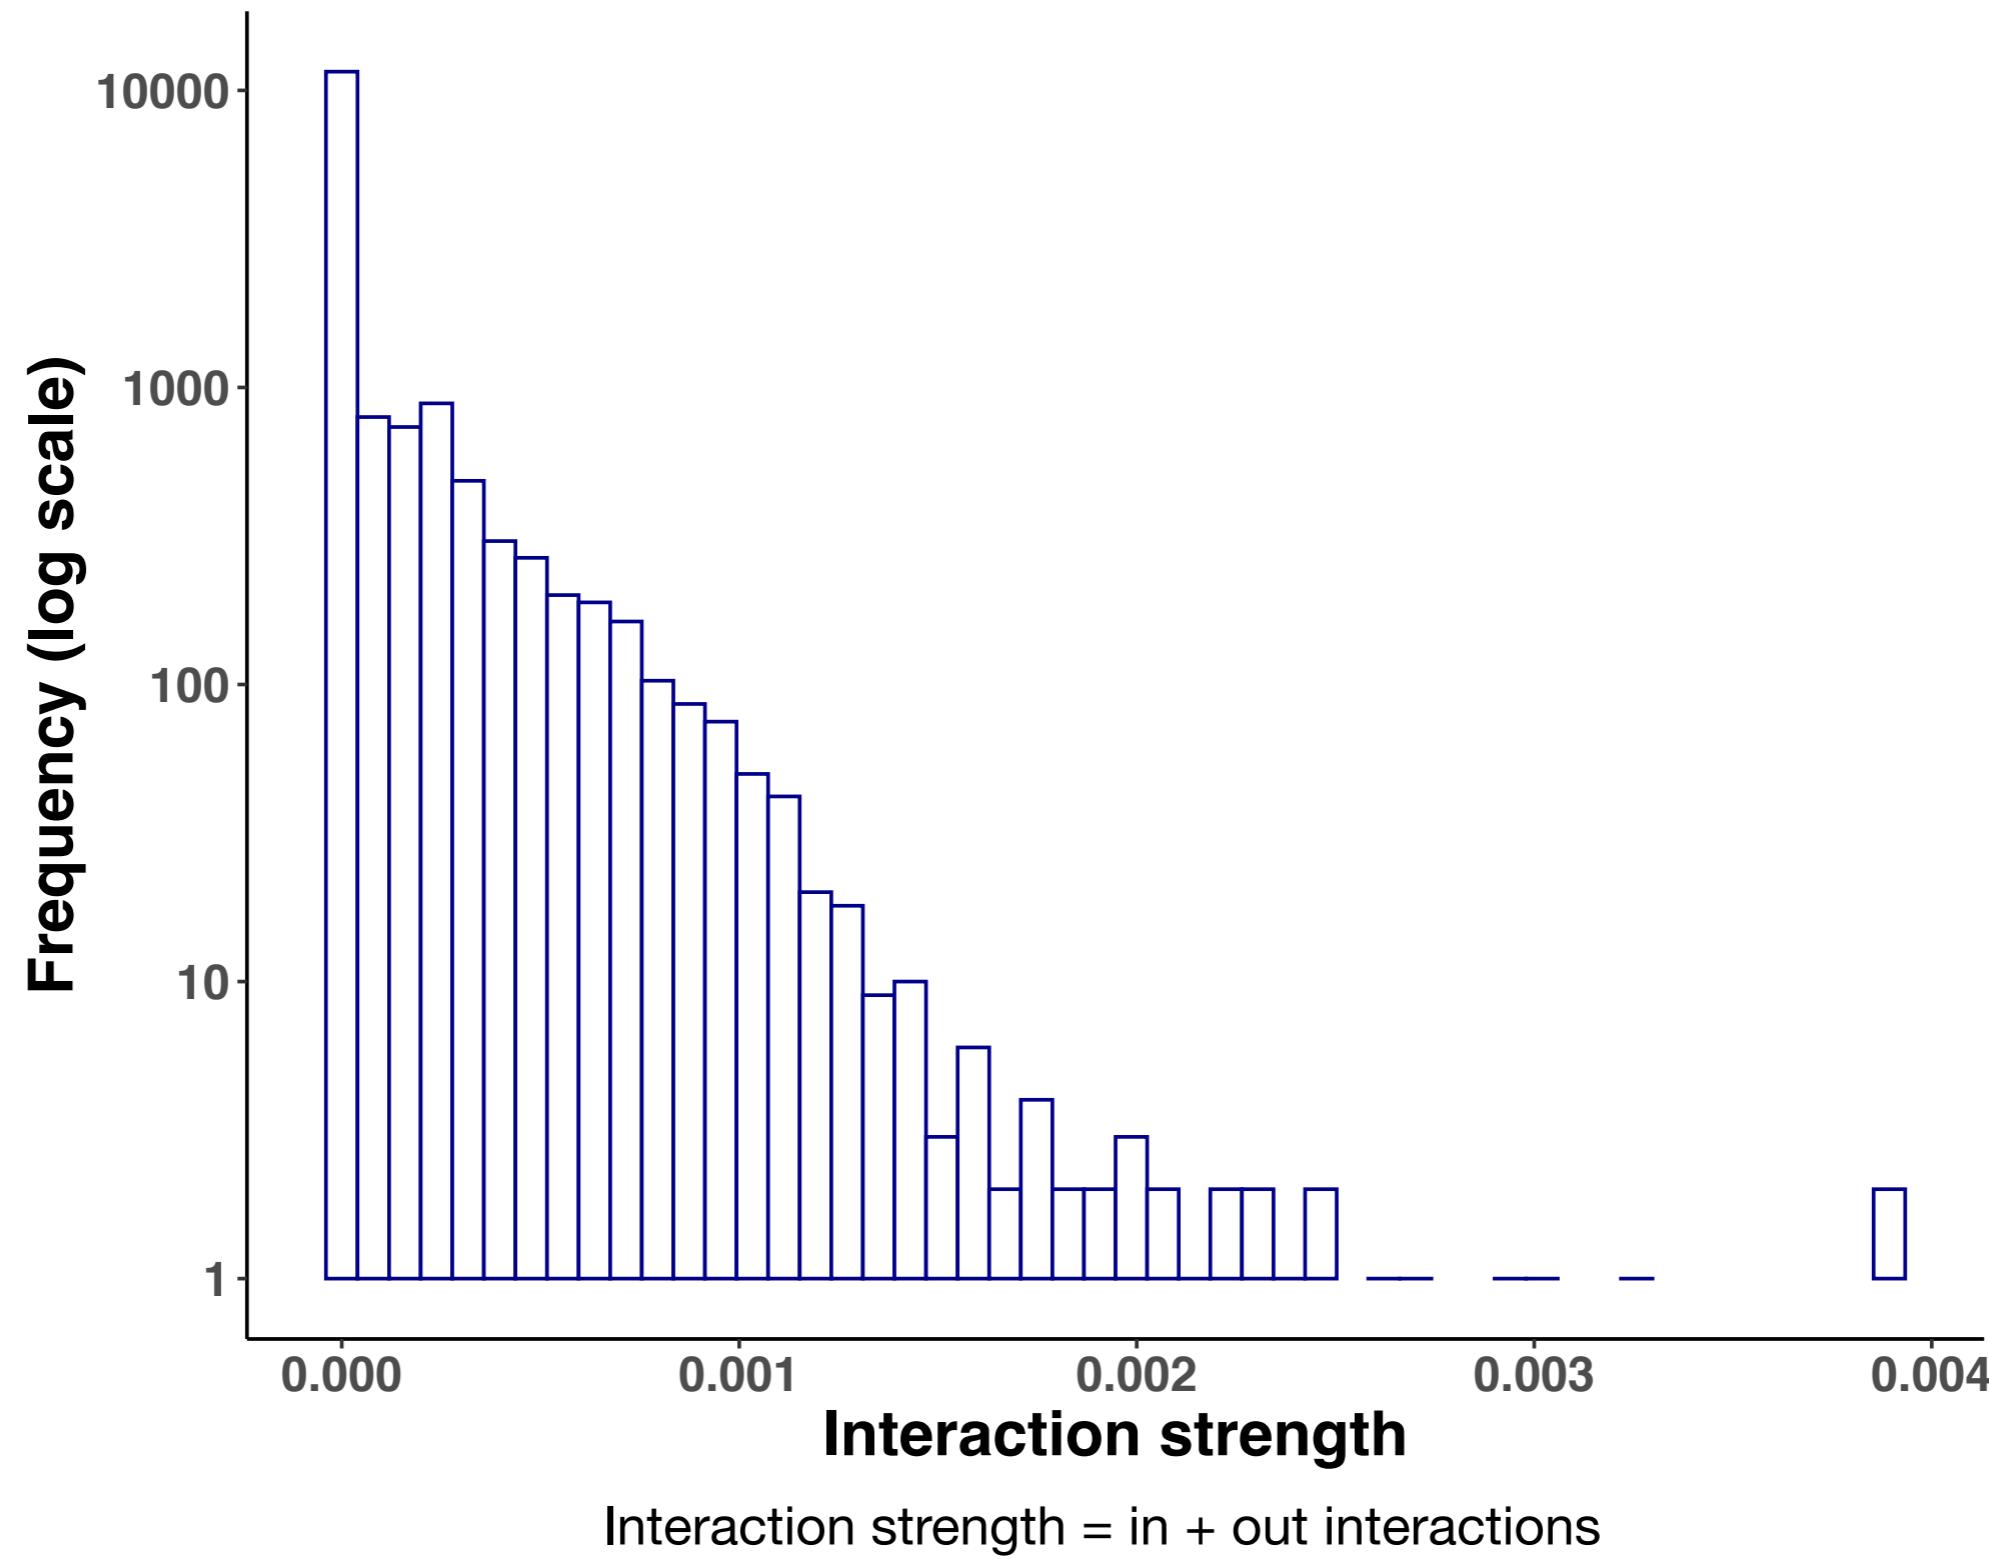

# **RESULTS**

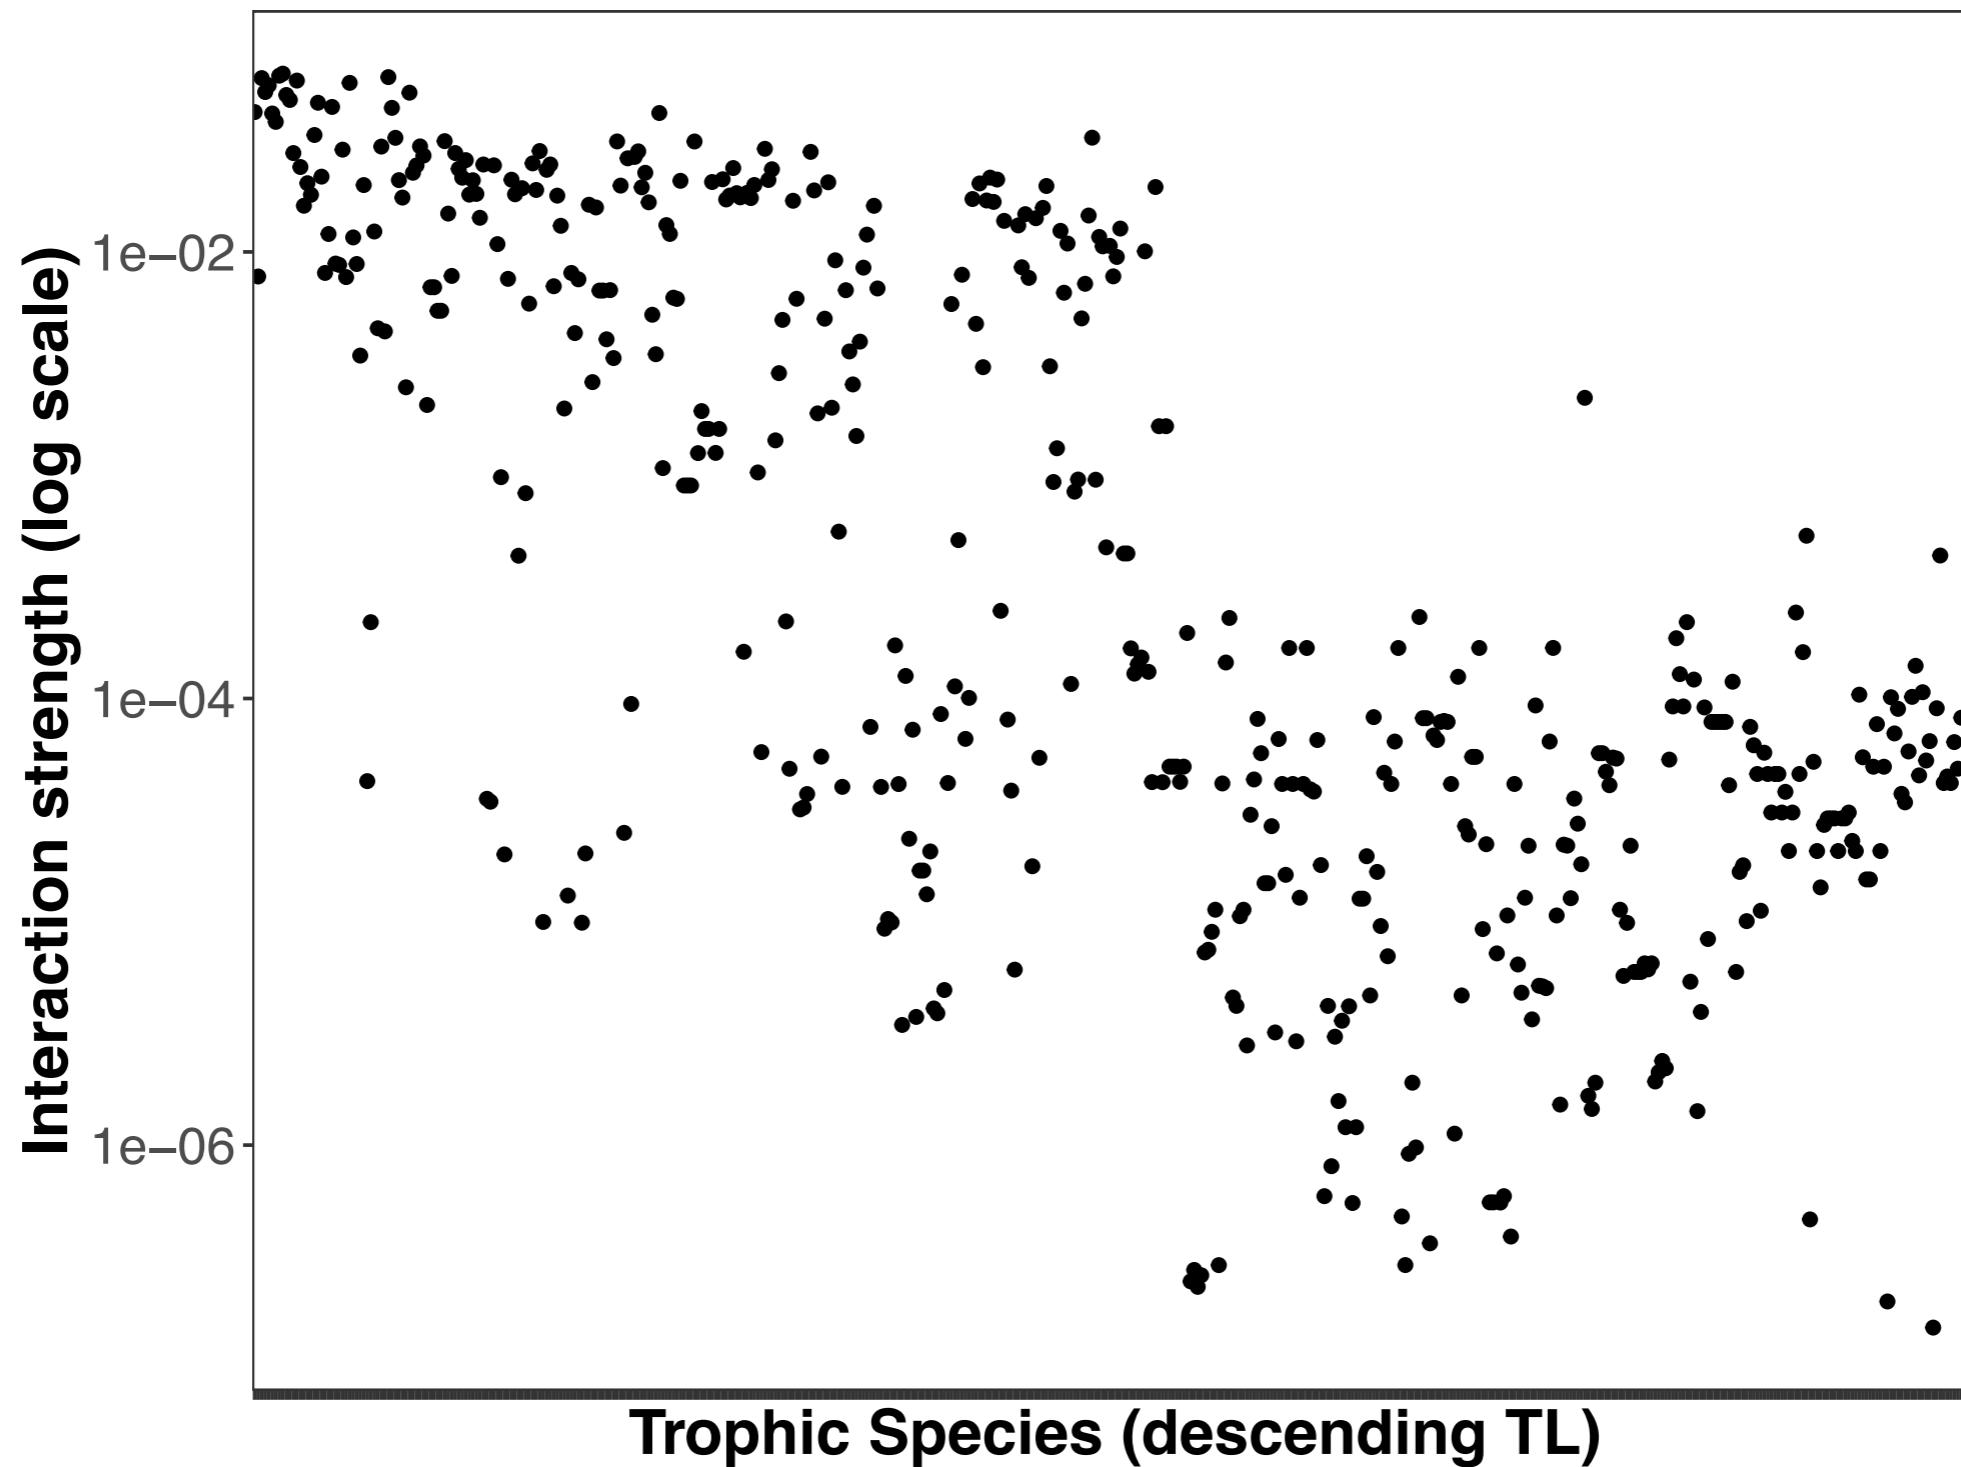

The Weddell Sea food web describes an ecosystem of **490 trophic species** and **16041 predator-prey interactions**

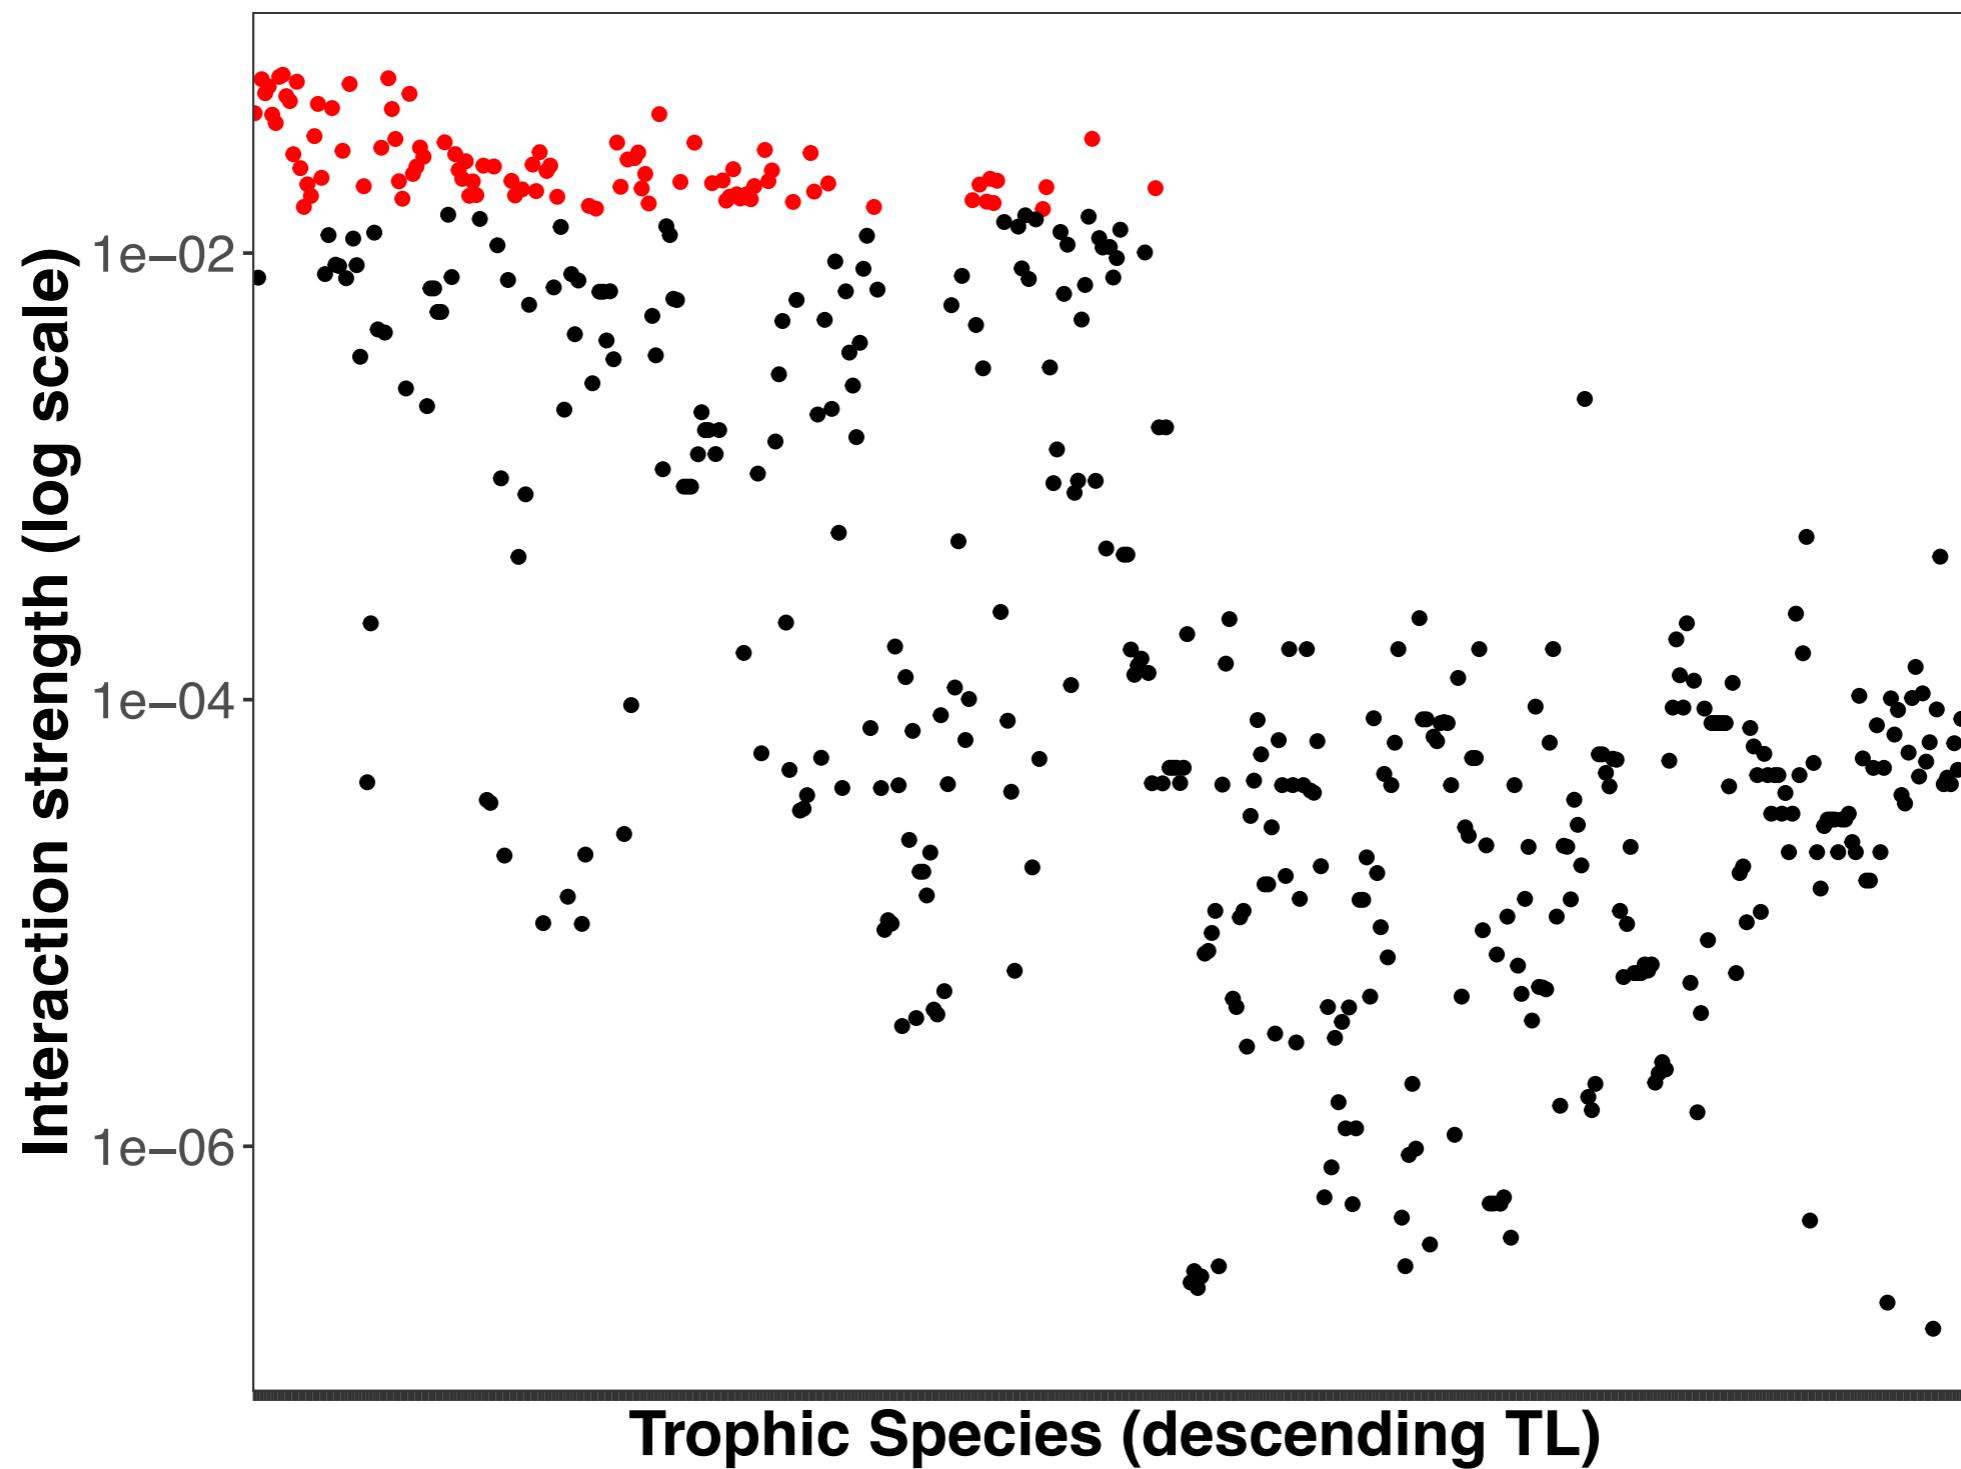

# Asymmetric distribution of the interaction strength: many weak interactions, few strong

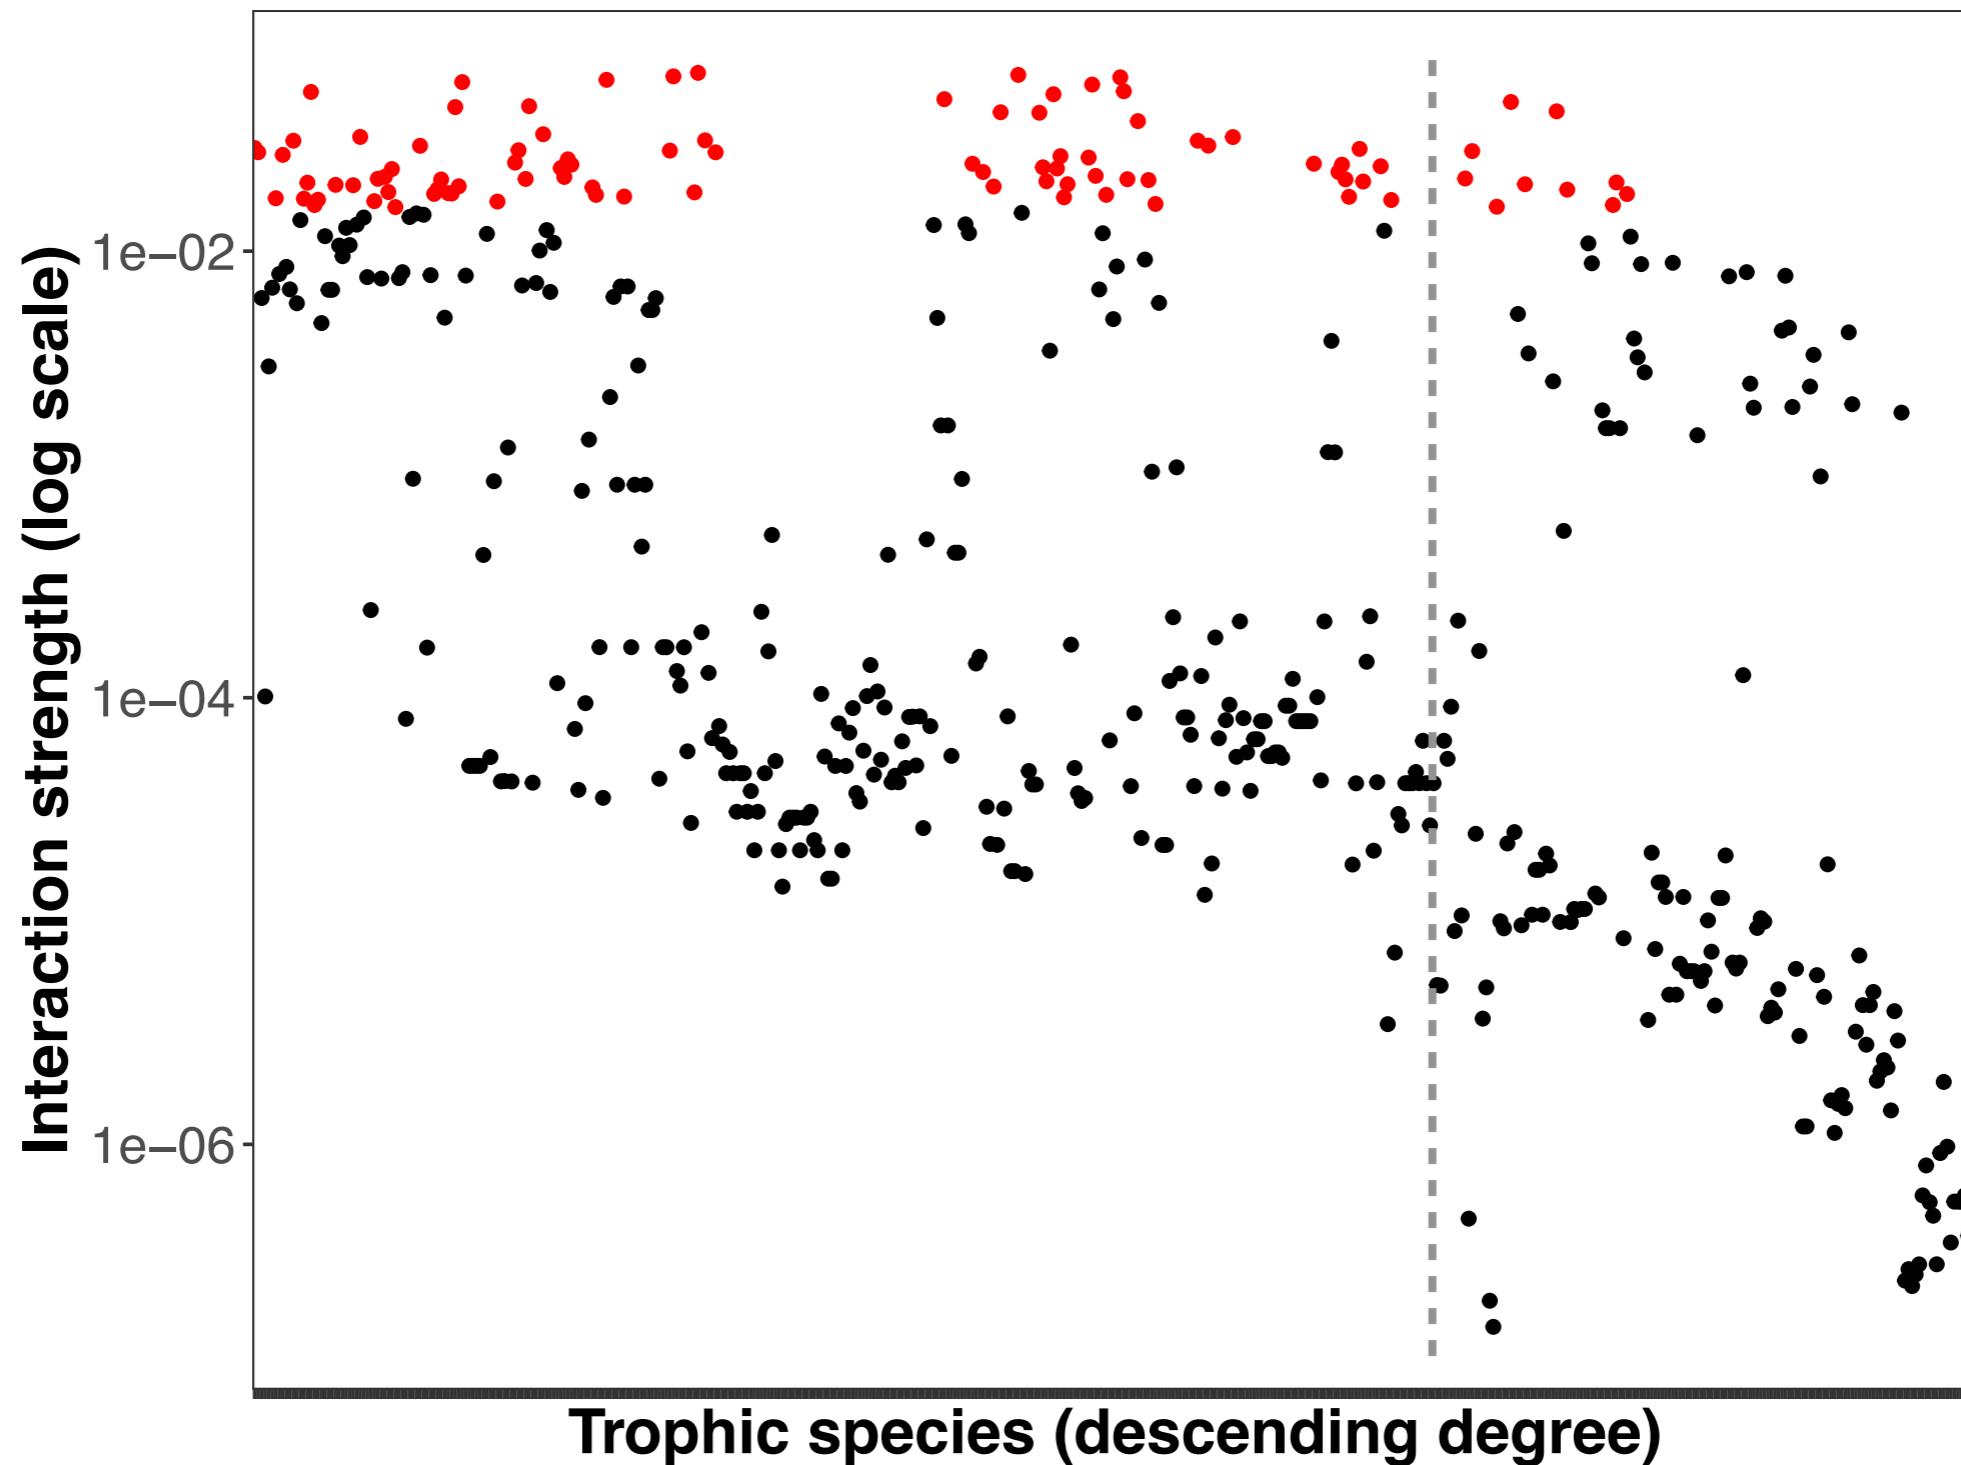

Evident relationship btw **interaction strength** and **TL**:  
**strong interactions in high-trophic level species**

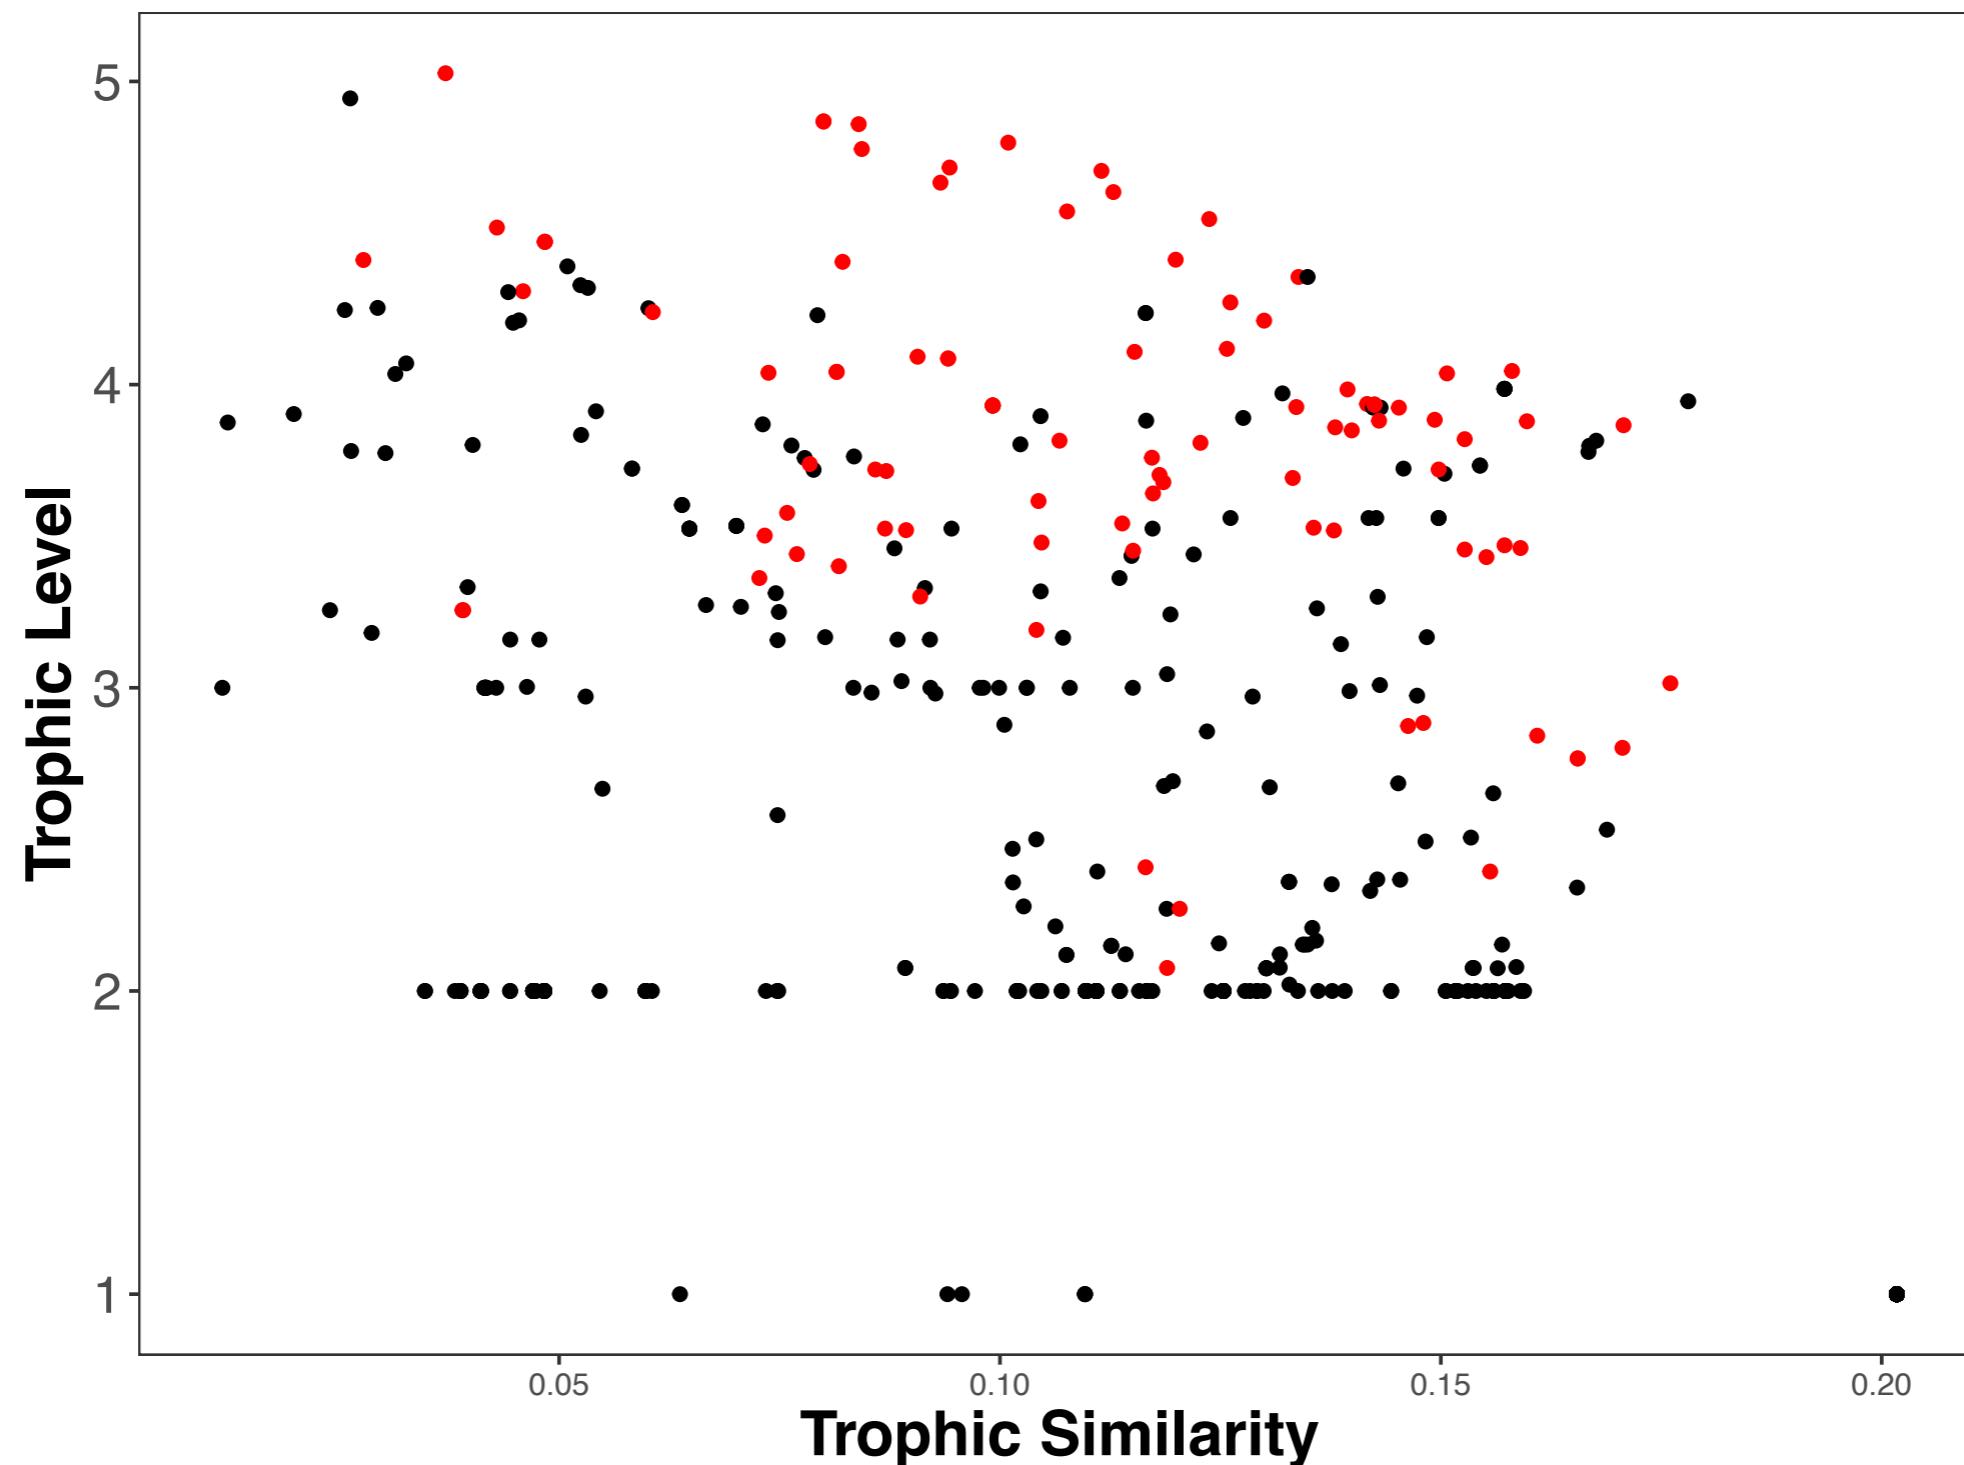

**20% of the species**  
**80% of the total interaction strength of the food web**

Relationship btw **interaction strength** and **degree**:  
**uniform until a degree threshold, when it decreases**

The species with **strongest interaction strength** (80%) are distributed all along the trophic similarity range in  $TL > 2$

# **CONCLUSION**

- ✓ Few species, 20%, hold most of the interaction strength of the food web, meaning that they are important to the stability of the ecosystem.
- ✓ Most of these important species are in high trophic levels (top predators), such as marine mammals and sea birds.
- ✓ These species may have many or few interactions, meaning that this parameter (degree) is not a good predictor of species importance to the stability of the ecosystem.
- ✓ Only few of these important species are unique in terms of trophic similarity, most of them present mid to high similarities.

**The Weddell Sea food web presents a high functional redundancy, where the most important species (strong interactions) are “replaceable”, suggesting stability to perturbations.**

Thank you for your  
attention!
